#### Abstract

In this paper we propose a new method of implementing a Single Sampling Plan by Variables (SSPV) when a lower specification limit is given. The idea is to utilize the information contained in the ( $1-\alpha$ ) \% confidence intervals (CI) of a) the process mean and b ) process variance in the place of their point estimates and a new test statistic Z is proposed assuming that the data follows normal distribution. Taking the lower, middle and upper values of the CI for each of the two parameters, we get 9 possible combinations to derive the Z statistic. We have proposed a method of weighted average of these 9 estimates and examined the quality of decision about sentencing the lot. It is shown by simulation that the new method gives better results than the method based on the point estimates.

Key words: Confidence Intervals, Specification Limit, Lot Acceptance Probability

## 1. Introduction

Single sampling plan for variable type of inspection (SSPV) is a classical concept in the field of acceptance sampling. The SSPV is specified as $(n, k)$ where $n$ denotes the sample size to be drawn from the lot and the lot is accepted or rejected basing on the outcome of the sample inspection. Let X be the quality characteristic following $\mathrm{N}\left(\mu, \sigma^{2}\right)$ and we assume that the production process is in a steady state capable of meeting the speciation limits.

Define $L$ as the lower specification limit such that any item for which the observed measurement $x \geq L$ is accepted.

Let $\overline{\mathrm{X}}=\sum_{\mathrm{i}=1}^{\mathrm{n}} \mathrm{X}_{\mathrm{i}}$ and $\mathrm{s}^{2}=\sum_{\mathrm{i}=1}^{\mathrm{n}} \frac{\left(\mathrm{x}_{\mathrm{i}}-\overline{\mathrm{x}}\right)^{2}}{(\mathrm{n}-1)}$ be the unbiased point estimates of $\mu$ and $\sigma^{2}$ respectively based on a sample data of $n$ observations. The classical method of implementing the sampling plan is to compute a statistic $\mathrm{Z}_{\mathrm{L}}=\frac{(\bar{x}-L)}{s}$
and the lot is accepted if $\mathrm{Z}_{\mathrm{L}} \geq k$ and rejected otherwise. The Operating Characteristic (OC) of the plan is the proportion of lots accepted at a given level of lot quality, expressed as $\mu$.

The basics of this plan can be found in Montgomery [1], Duncan [2] and Grant and Leavenworth [3]. In general we will not be knowing the true mean or variance of the process but proceed with prior knowledge or from process history by computing the sample mean and variance as point estimates. The value of $Z_{L}$ is sensitive to the values of $\bar{x}$ and $s$ and as such the lot sentencing depends on how good these values are known.

In this paper we propose a new method of estimating the lot quality taking into account the interval estimates of $\mu$ and $\sigma^{2}$ and generate a new expression in the place of $\mathrm{Z}_{\mathrm{L}}$.

## 2. The confidence intervals of $\mu$ and $\sigma^{2}$

Let $f(x, \theta)$ be the density function of $X$ and $\theta$ be estimated from a sample $\left\{x_{1}, x_{2}, \ldots, x_{n}\right\}$ drawn from $f(x, \theta)$. Then the $100(1-\alpha) \%$ interval estimate of $\theta$ will be [ $\widehat{\theta}_{L}, \widehat{\theta}_{U}$ ] where $\widehat{\theta}_{\mathrm{L}}$ and $\widehat{\theta}_{\mathrm{U}}$ denote the lower and upper bounds of the CI. (see Rohatgi [4]). We denote these bounds by $\theta_{1}$ and $\theta_{3}$, which can be considered as extreme estimates of $\theta$ and define $\theta_{2}$ as the value at the middle of the CI. Then from the confidence interval one gets three possible estimates of $\theta$ viz., $\theta_{1}, \theta_{2}$ and $\theta_{3}$, out of which $\theta_{2}$ is likely to be closer to $\theta$ than the other two. In the light of this approach we get three estimates for $\mu$ and three for $\sigma$ so that there will be 9 possible combinations at which (1) can be evaluated. We call this the triple estimate method. Further, each combination is a candidate for lot sentencing. We wish to combine them into a single value and examine its properties.

Since $\overline{\mathrm{X}}$ follows $\mathrm{N}\left(\mu, \sigma^{2} / n\right)$ the (1- $\alpha$ )\% Confidence Interval (CI) for $\mu$ is given by

$$
\begin{equation*}
\left\{\overline{\mathrm{x}}-\mathrm{t}_{(n-1), \alpha / 2} \frac{\mathrm{~s}}{\sqrt{n}}, \overline{\mathrm{X}}+\mathrm{t}_{(n-1), \alpha / 2} \frac{\mathrm{~s}}{\sqrt{n}}\right\} \tag{2}
\end{equation*}
$$

where $\mathrm{t}_{(n-1), \alpha / 2}$ denote the upper $\alpha / 2^{\text {th }}$ percentile of the Student's t-distribution with ( $n-1$ ) degree of freedom.

The value of $\mu$ is unknown but on an average it is equal to $\overline{\mathrm{X}}$. However, the true value of $\mu$ lies in the interval given in (1) with probability $(1-\alpha)$.

Similarly let $\chi_{\alpha / 2}^{2}$ and $\chi_{1-\alpha / 2}^{2}$ denote the lower and upper $\alpha / 2$ percentiles on the Chi-square distribution. These values can be found by using simple Excel functions. Then for the process $\sigma^{2}$, the $100(1-\alpha) \%$ CI, based on the Chi Square distribution is given by
$\left\{\frac{(n-1)}{\chi_{\alpha / 2}^{2}} s^{2}, \frac{(n-1)}{\chi_{1-\alpha / 2}^{2}} s^{2}\right\}$.

Again the true value of $\sigma^{2}$ lies in (3) with probability (1- $\alpha$ ). The width of the CIs in both (2) and (3) depends on the values of $\bar{x}$ and $s$. The following are the lower, middle and upper values of the estimates for $\mu$.
$m_{1}=\overline{\mathrm{x}}-t_{(n-1), \alpha / 2} \frac{s}{\sqrt{n}}, m_{2}=\overline{\mathrm{x}}, m_{3}=\overline{\mathrm{x}}+t_{(n-1), \alpha / 2} \frac{s}{\sqrt{n}}$
and the estimates for $\sigma$ are
$\mathrm{s}_{1}=\sqrt{\frac{(n-1)}{\chi_{\alpha / 2}^{2}} s^{2}}, \mathrm{~s}_{2}=\sqrt{s^{2}}, \mathrm{~s}_{3}=\sqrt{\frac{(n-1)}{\chi_{1-\alpha / 2}^{2}} s^{2}}$.
This method of summarizing confidence intervals to generate the criterion was earlier used by Vishnu Vardhan et al [6],[7] while trying to estimate the area under the ROC curve. Sai Sarada et al [5] have used this method and obtained a new expression for estimating the process capability index of a process following normal distribution. In the following section, we derive a pooled estimate of $\mathrm{Z}_{\mathrm{L}}$ by utilizing the information from the 9 -combinations of estimates of $\mu$ and $\sigma$.

## 3. New method of implementing the SSPV

Consider a characteristic X for which the lower specification limit is given as L. For any item, if the observation x on X satisfies the condition $\mathrm{x} \leq \mathrm{L}$, the item is considered as defective. Let $\alpha$ denotes the producer's risk and define $k=\mathrm{Z}_{\alpha}=\phi^{-1}(\alpha)$ be the value of standard normal distribution at $\alpha$ where $\phi$ denotes the cumulative standard normal distribution. The general procedure for decision making (Duncan[2]) is as follows.

1. Find $\mathrm{Z}_{\mathrm{L}}=\frac{(\bar{x}-L)}{s}$
2. Calculate $k=\phi^{-1}(\alpha)$
3. Accept the lot if $\mathrm{Z}_{\mathrm{L}} \geq k$; else reject.

Consider the following propositions.
Propositon-1: Define $\mathrm{Z}_{\mathrm{ij}}=\frac{\left(\overline{\mathrm{x}}_{\mathrm{i}}-L\right)}{s_{j}}$ as the standard normal deviate defined at the combination ( $\bar{x}_{\mathrm{i}}, \mathrm{s}_{\mathrm{j}}$ ) for $\mathrm{i}, \mathrm{j}=1,2,3$.
Then the new test statistic is given as
$\mathrm{Z}_{\text {pooled }}=\sum_{\mathrm{i}=1}^{3} \sum_{\mathrm{j}=1}^{3} \mathrm{w}_{\mathrm{ij}} \mathrm{z}_{\mathrm{ij}}$
where $\mathrm{w}_{\mathrm{ij}}$ is the weight given to $\mathrm{Z}_{\mathrm{ij}}$. The decision rule is to accept the lot if $\mathrm{Z}_{\text {pooled }}>k$; else reject.

Propositon-2: We can alternatively define in the one dimensional space, $\left\{\mathrm{Z}_{1}, \mathrm{Z}_{2}, \mathrm{Z}_{3}, \mathrm{Z}_{4}, \mathrm{Z}_{5}, \mathrm{Z}_{6}, \mathrm{Z}_{7}, \mathrm{Z}_{8}, \mathrm{Z}_{9}\right\}$ as the vector of the 9 estimates and take its scalar product with the weight vector $\left\{W_{1}, W_{2}, W_{3}, W_{4}, W_{5}, W_{6}, W_{7}, W_{8}, W_{9}\right\}$. When the sum of weights is unity, then $\mathrm{Z}_{\text {pooled }}$ will be a convex combination of the 9 individual values. Further, it can be shown that $\mathrm{Z}_{\text {pooled }} \leq \operatorname{Max}\left\{\mathrm{Z}_{\mathrm{ij}}\right\}$.

Propositon-3: One way of allotting the weights is to allot 0.5 to $\mathrm{Z}_{5}$ where both the point estimates are used and the remaining 8 weights can be taken as $0.5 / 8$ each. The vector of weights in this case will be
$\mathrm{W}=\{0.0625,0.0625,0.0625,0.0625,0.5,0.0625,0.0625$, $0.0625,0.0625\}$.

Propositon-4: Define $\mathrm{Z}_{0}=$ target value of Z obtainable when the process operates at $\mu$ and $\sigma$. Then an objective way of allotting the weights is to take
$W_{j}=\left(Z_{j}-Z_{0}\right)^{-2} \quad$ for $\mathrm{j}=1$ to 9 .

This means that the weights are proportional to the inverse of the squared error in $\mathrm{Z}_{\mathrm{j}}$ from the target $\mathrm{Z}_{0}$. These weights are in a way adaptive and depend on the sample data.

In the following section, we conduct simulated trials and study the properties of the new decision rule based on $\mathrm{Z}_{\text {pooled }}$. We also find the operating characteristic (OC) by empirically finding $\mathrm{P}\left(\mathrm{Z}_{\text {pooled }}>\mathrm{k}\right)$.

Let us consider a hypothetical sampling plan with $\mathrm{n}=20$, k $=2.17009$ with producer's risk as $\alpha=0.015$ assuming that the variance is unknown.

## Algorithm

The following steps can be followed to implement the new method.

1. Generate $m$ random samples each of size $n=20$ from $\mathrm{N}\left(\mu, \sigma^{2}\right)$.
2. Evaluate the sample $\overline{\mathrm{X}}$ and s for each sample.
3. Find the three estimates of $\mu$ as $m_{1}, m_{2}$ and $m_{3}$ and three estimates of $\sigma$ as $s_{1}, s_{2}$ and $s_{3}$ using (4) and (5)
4. Find $\mathrm{Z}_{\text {pooled }}$ using (6) and (8).
5. For each sample (lot), mark ' $A$ ' if $Z_{\text {pooled }}>k$, to indicate acceptance of the lot and mark R (rejected) otherwise and find the proportion of A's out of $m$.

If $m$ lots are tested with this plan, the proportion of lots accepted is an estimate of the lot acceptance probability $\widehat{P}(\mathrm{~A})=r / m$ where $r$ denotes the number of lots accepted by the plan and $m$ is the total number of lots inspected. Since each lot has a binary outcome, the standard error of this estimate is $\sqrt{\widehat{P}(\mathrm{~A})(1-\widehat{P}(\mathrm{~A})) / m}$. This $\widehat{P}(\mathrm{~A})$ produces different values at the 9-estimates of Z and also at $\mathrm{Z}_{\text {pooled }}$.

In the following section a simulated experiment is reported along with a template in Excel to demonstrate the working of the new method.

## 4. Illustration

Consider a situation where X follows normal with $\mu=10.8$ and $\sigma=1.5$. Let the lower specification limit $(\mathrm{L})$ is given as 7.0. We have generated 30 samples each of size 20 from the above normal distribution using the Random Number Generation tool of the Data Analysis Pak in Excel. The confidence intervals are generated by taking $\alpha=0.05$. The Excel function CONFIDENCE $(0.05,1.5,20)$ has been used to derive the lower and upper limits.

The three estimates of means and standard deviations each based on the $95 \%$ confidence intervals are worked out using Excel template. Assuming that the process truly operates at $\mu=10.8$ and $\sigma=1.5$, the Z statistics in relation to L will be the target Z (denoted by $\mathrm{Z}_{0}$ ) obtainable when samples are randomly drawn from this process. In this case $\mathrm{Z}_{0}$ becomes 2.5333.

Since we have fixed the producer's risk at $\alpha=0.015$ we get $\mathrm{k}=2.17009$. Table-1 shows the adaptive weights for each of the 9 values of Z and $\mathrm{Z}_{\text {pooled }}$ is computed. The rule is to accept the lot if $\mathrm{Z}_{\text {pooled }} \geq \mathrm{k}$. For each lot we have computed
the decision to accept or reject (marked as A or R in the sheet with a condition " $=\operatorname{IF}(A N 11>\$ A P \$ 1, " A ", " R ")$ ".

We have also computed the decision outcome using $\mathrm{Z}_{22}$ as done conventionally and compared the decision from these two methods. The proportion of accepted lots is found and its standard error is also reported.

In the Figure-1, the heading des1 refers to Probability of accepting the lot basing on $\mathrm{Z}_{\text {pooled }}$ and des2 refers to Probability of acceptance basing on $\mathrm{Z}_{22}$ (which is the same as $Z_{5}$ ).
We have repeated the above experiment with 500 samples each and the results are summarized in Table-1.

From the above experiments we observe the following.

1. The new estimate $\mathrm{Z}_{\text {pooled }}$ provides Z values closer to the target when compared with the conventional point estimate method given by $\mathrm{Z}_{22}$.
2. At different values of the process mean, $\mathrm{Z}_{\text {pooled }}$ is less than $\mathrm{Z}_{22}$

Table-1: Performance of $\mathrm{Z}_{\text {pooled }}$ method in comparison with the classical Z method from 500 simulations ( $\mathrm{n}=20, \mathrm{k}=2.170$ )

| Criterion value | $\begin{gathered} \text { Mean }=10.2, \mathrm{SD}=1.5 \\ \mathrm{Z}_{0}=2.1333 \end{gathered}$ |  |  | $\begin{gathered} \text { Mean }=10.5, \mathrm{SD}=1.5 \\ \mathrm{Z}_{0}=2.3333 \end{gathered}$ |  |  | $\begin{gathered} \text { Mean }=10.8, \mathrm{SD}=1.5 \\ \mathrm{Z}_{0}=2.5333 \end{gathered}$ |  |  |

## 4. Analysis of simulations

We have performed a detailed analysis of the output from 500 simulations. Each trial represents a lot from which 20 samples were drawn at random from $\mathrm{N}(10.5,1.5)$ with lower specification limit $\mathrm{L}=7.00$. The target value which we expect to get out of random samples from the process will be $\mathrm{Z}_{0}=2.3333$.

A run chart was also constructed for the 500 individual values of $Z_{22}$ and $Z_{\text {pooled }}$ which shows that $Z_{\text {pooled }}$ is more consistent than $\mathrm{Z}_{22}$. The mean of $\mathrm{Z}_{22}$ is 2.5094 with 3 sigma control limits as (1.0607, 3.9583) and 4 samples (lots) out of 500 have shown out of control.

In the case of $\mathrm{Z}_{\text {pooled }}$ the mean is 2.3306 with 3 sigma control limits as $(2.1593,2.5019)$ and only one out of 500 samples fell out of control. We find that 3 samples (lots) out
of 500 have shown out of control. Similar results are found when the process mean has shifted to left (10.2) and to the right (10.8).

Kolmogorov- Smirnov test for normality of $\mathrm{Z}_{22}$ and $\mathrm{Z}_{\text {pooled }}$ has shown that $\mathrm{Z}_{\text {pooled }}$ is closer to normality ( $\mathrm{p}=0.546$ ) than $\mathrm{Z}_{22}(\mathrm{p}=0.078)$ confirming that the new statistic has a good normal distribution.

Figure-2 gives the Box plot of the distribution of $\mathrm{Z}_{22}$ and $\mathrm{Z}_{\text {pooled }}$ which shows that the distribution of $\mathrm{Z}_{\text {pooled }}$ has lower dispersion when compared to that of $\mathrm{Z}_{22}$ though both statistics have few extreme values. We therefore conclude that the new estimated $Z_{\text {pooled }}$ offers a better estimate of the test criterion instead of $\mathrm{Z}_{\text {pooled }}$.

## Conclusions

It is observed that the new criterion ( $\mathrm{Z}_{\text {pooled }}$ ) which is the weighted of Z values obtained from the 9 possible combinations of the estimates of mean and variance, has lower standard error than single Z value based on the point estimates. Hence we recommend the use of Confidence Interval based decision rule in place of the conventional method based on point estimates.

## Acknowledgements

The authors wish to thank Prof. Rao. S. Jammalamadaka, University of California, for his valuable suggestions and directions on a draft version of the method proposed in this paper.
