ABSTRACT

This study was carried out to assess the effect of Municipal Solid Waste (MSW) leachate on ground water quality in Port Harcourt, Nigeria. Cross sectional study was conducted around two dumpsites in Port Harcourt, Nigeria on leachates and borehole water. Concentrations of some physiochemical parameters such as pH, Total Dissolved Solids (TDS), Biochemical Oxygen Demand (BOD), Chemical Oxygen Demand (COD), Electrical Conductivity (EC), Nitrite ion, Phosphate ion, Sulphate ion, Chloride ion; and heavy metals (Cd, Pb, Zn, Fe, and Cu) were determined in the leachate and borehole water (close to, and about 10 km away from the dumpsite). The result shows that some parameters in the borehole water did not meet the standards of WHO and NSDWQ; and most leachates and borehole water qualities near the unengineered dumpsites are of poor quality. There was a decreasing trend in concentrations of hazardous contaminants from the leachate to nearby borehole water and eventually the distant borehole water. This shows that the leachates exert great effect on the concentrations of contaminants in the surrounding borehole waters and distant ones. The result indicated that the dumpsite leachate is producing many potent contaminants to the environment and to the people nearby. Concerned authority should therefore take appropriate intervention measures for conserving the groundwater.

Keywords: Municipal, Groundwater, Waste management, Leachate

1. INTRODUCTION

Municipal Solid waste leachate is a highly complex effluent which contains dissolved organic matters, inorganic compounds such as ammonium, calcium, magnesium, sodium, potassium, iron, sulphates, chlorides and heavy metals such as cadmium, chromium, copper, lead, zinc, nickel and xenobiotic organic substances (Christensen *et al*., 2001). This leachate accumulates at the bottom of landfill and percolates through the soil (Mor *et al*., 2006).

Rapid population growth and development in Nigerian states has resulted in environmental health hazards (Adefemi and Awokunmi, 2009). Wastes are generated from human activities and in most cases not properly managed in most Nigerian cities (Aurangabadkar *et al*., 2001; Adefemi and Awokunmi, 2009). This leads to low environmental quality which accounts for 25% of all preventable ill health in the world (WHO, 2004). In most cases, wastes are collected and disposed in uncontrolled or unengineered dumpsite sites near residential buildings. These wastes are heaped up and/or burnt, polluting the environment (Akpan, 2004; Uffia *et al*., 2013). Leachates from dumpsites constitute a source of heavy metal pollution to both soil and aquatic environments (Ali and Abdel-Satar, 2005). Water contaminants have been mainly biological and chemical in origin (Uffia *et al*., 2013). The quality of underground water is compromised by the indiscriminate dumping of waste in the environment and contamination by leachate. (David and Oluyege, 2014).

Waste generated from Port Harcourt metropolis is disposed of directly into random 'borro' pits close to streams, valleys, open fields, water lands without adequate handling and treatment (RSESA, 2013). In Port Harcourt today, wastes generated and gathered at source are disposed of in communal bins or communal collection points stipulated by the Government. Most of these wastes appear to come from domestic sources and are characterized mostly by household waste. Generally, the practices at unengineered dumpsites in Port Harcourt are unrestricted to different sources of wastes; dumpers have access to the site at any time of the day, which increase dumping of restricted materials, such as car batteries and metals. Scavengers have free access to the dump, and they scatter the waste to recover valuable material. Some scavengers even pitch their tent in and around the unengineered dumpdites. One of the major environmental problems at unengineered dumpsites is the loss of leachates from the site and subsequent contamination of groundwater (Jagloo, 2002).

Ogedengbe and Akinbile (2007) reported that high turbidity of water samples is due to the infiltration of leachate from the dumpsites into the wells or borehole. The contaminants are largely soluble compounds and microorganisms (Aderiye *et al*., 1992; Udoessien, 2004). Heavy metals are not commonly found in groundwater, their presence is largely as a result of environmental contamination (Bahnasawy *et al*., 2011). Urban wastes constitute a large source of pollution and have a significant impact on the ecosystem (Adebayo *et al*., 2007; Edema *et al*., 2001; Pirsaheb *et al*., 2013).

The risk of ground water pollution is probably the most severe environmental impact from dumpsite because historically, most dumpsites are without engineered liners and leachate collection and treatment systems (Christenen and Kjeldsen, 1995). Leachate may also contain hazardous and non-hazardous substances that can be found in most groundwater systems. These include dissolved metals (e.g., iron and manganese), salts (e.g., sodium and chloride), and abundance of common anions and cations (e.g., bicarbonate and sulphate). Several studies revealed that impacts of exposure to nearby residents can cause still birth, low birth weight, congenital malformation, Cancer and other public health problems (Elliot, *et al* 2001, Flieder, *et al*. 2000, and Goldberge *et al*. 1999). The aim of this work therefore is to assess the effect of Municipal Solid Waste (MSW) leachate on groundwater quality in Port Harcourt, Nigeria.

2. MATERIALS AND METHOD

Study Area

Cross-sectional study of selected refuse dumpsite was conducted in Port Harcourt, Nigeria to assess the effect of Municipal Solid Waste (MSW) leachate on ground water quality in Port

Harcourt, Nigeria. Port Harcourt is the capital and largest city in Rivers State, Nigeria. It is located in the Niger-Delta region; and at the southernmost part of Nigeria between longitude $7^0 00^/$ and $7^0 15^/$ East of the Greenwich meridian and Latitude of $4^0 30^/$ and $4^0 47^/$ North of the equator Fig 1. The average temperature throughout the year in the city is relatively constant, showing little variation throughout the year. Its average temperature is between 25^0C – 28^0C.

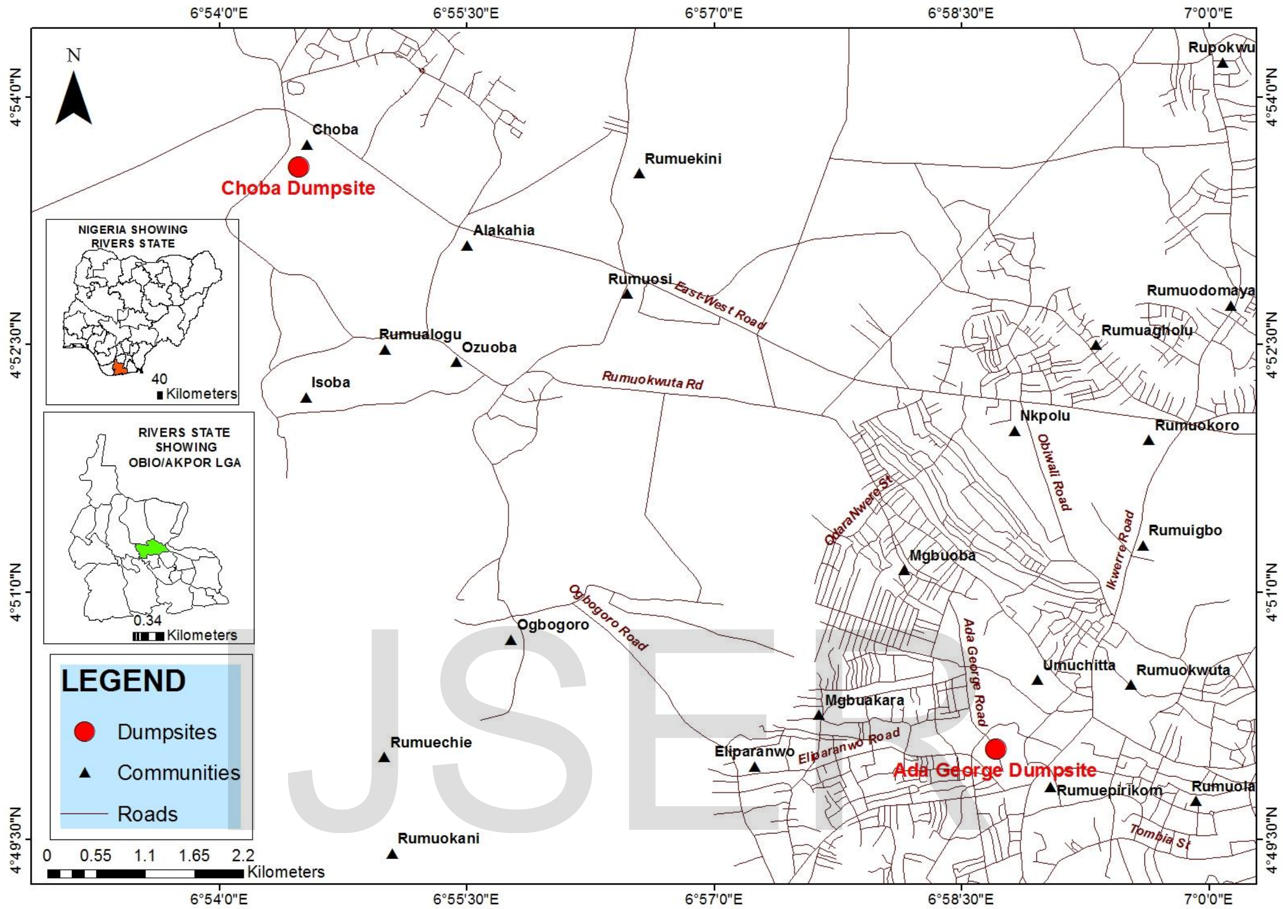

Figure 1: Map of study area

2.2 Sampling Method

Two samples of leachates and borehole water each were collected at and around two unengineered dumpsites in Port Harcourt, Nigeria for laboratory analysis. In an effort to study the extent of groundwater contamination, sampling points were selected within the dumpsite from where the borehole water samples were collected. The samples were collected in clean plastic bottles after the extraction of water from borehole. The water was left to run from the source for about 4 minutes to flush out the water that stood in the borehole and enable the collection of representative samples. Attempts were made to minimize changes in the chemistry of the samples. Refrigeration and protection from light were adopted to assist in maintaining the natural chemistry of the samples. These conditions were maintained until the samples were received at the laboratory. Samples were stored in refrigerator at 4^0C. Sampling plan was coordinated with the laboratory so that appropriate sample receipt, storage, analysis, and custody arrangements were provided. All the samples were analyzed for relevant physicochemical parameters according to internationally accepted procedures and standard methods for examination of water and wastewater (APHA, 2012). Parameters tested in leachate and borehole water samples include pH, electrical conductivity (EC). Nitrite (NO_3^-), Phosphate (PO_4^-), Chloride (Cl^-), Sulphate (SO_4^{2-}), Cadmium (Cd), Lead (Pb), Zinc (Zn), Iron (Fe), Copper (Cu), Biological Oxygen Demand (BOD), Chemical Oxygen Demand (COD) and Total Dissolved Solids (TDS). Geomorphological study of the region indicates that most of the area where the unengineered dumpsites were located was found to have deep pediments, with shallow and buried pediments in other parts. The samples were analysed and three quality tools/indices were applied in this study. These are:

1. Water Quality Index (WQI)
2. Contamination Factor (CF)
3. Contamination Degree (CD)

Water Quality Index (WQI)

Water quality index (WQI) represents water quality assessment through the determination of physicochemical parameters of Ground water; it can act as an indicator of water pollution because of natural inputs and anthropogenic activities (Yisa and Jimoh, 2010). WQI is one of the most effective tools to provide feedback on the quality of water to the policy makers and environmentalists. It provides a single number expressing overall water quality status at a certain time and location. It is actually the categorization counting the combined influence of different important water quality parameters; as it is calculated based on the concentration of several important attributes (Sengupta and Dalwani, 2008)

Three steps followed for computing water quality index were:

In the first step, each of the parameters was assigned a weight (wi) according to its relative importance in the overall quality of water for drinking purposes. A maximum weight of 5 has been assigned to the parameter nitrate due to its major importance in water quality assessment (Ramakrishniah *et al*., 2009). Zinc and phosphate which are given weight of 1 by themselves may not be that harmful (APHA, 2012).

In the second step, relative weight (Wr) was computed from the following equation:

$$\mathbf{wr} = \frac{\mathbf{wi}}{\sum_{\mathbf{i-I}}^{\mathbf{n}} \mathbf{wi}}$$

Where

wr is the relative weight,
wi is the assigned weight of each parameter and
'n' is the number of parameters.

In the third step, a quality rating scale (qi) for each parameter was assigned by dividing its concentration in each water sample by its respective standard according to the guidelines laid down in the NSDWQ – Nigerian Standard for Drinking Water Quality (which conforms with WHO standard) and the result is multiplied by 100:

$$\mathrm{qi} = \frac{\mathrm{Ci}}{\mathrm{Si}} X\ 100$$

Where qi is the quality rating, Ci is the concentration of each parameter in each water sample in mg/l, and Si is the NSDWQ water standard for each chemical parameter in mg/l according to the guidelines of the Nigerian Standard for Drinking Water Quality (NSDWQ, 2007); and World Health Organisations (WHO, 2011). For computing the WQI, the sub index (SIi) was first determined for each parameter, which is then used to determine the WQI as per the following equation:

SIi = **wr** * qi

WQI = Σ SIi

SIi is the sub index of I[th] parameter, qi is the rating based on concentration of i[th] parameter and n is the number of parameter. WHO, (2006), stated that the computed WQI values are classified into five types “excellent water”, “good water”, “poor water” “very poor water” and “water unsuitable for drinking” as shown in Table 1.

Table 1. Water quality classification based on WQI value (WHO, 2006)

WQI Value	Water Quality
<50	Excellent
50 – 100	Good
100 – 200	Poor
200 – 300	Very poor
>300	Water unsuitable for drinking

Source: WHO, 2006)

Contamination Factor (CF)

Contamination factor is used to determine the concentration status of metal in the present study. Contamination factor was calculated by comparing the mean of heavy metal concentration with average shale or background concentration given by Turekian and Wedepohl (1961), which is used as global standard reference for unpolluted sediment. The CF is the single element index. CF for each metal was determined according to Thomilson, *et al*. (1980) by the following equation:

$$\text{Contamination Factor (CF)} = \frac{\text{Mean Metal Concentration at Contaminated Site}}{\text{Metal Average Shale Concentration}}$$

Hakanson (1980) classified CF values into four grades, i.e,

a) CF < 1 = low CF,
b) 1 $\leq$ CF > 3 = moderate CF,
c) 3 $\geq$ CF < 6 = considerable CF and
d) CF > 6 = very high CF.

Contamination Degree (CD)

Contamination degree is used to determine the degree of overall contamination or concentration status of heavy metals in the sampling site. CD is the sum of all CF values of a particular sampling site (Aksu *et al*., 1998 and Hakanson, 1980).

$$CD = \sum_{i=I}^{i=n} (CF)$$

Where n is the number of analysed elements and CF is the contamination factor.
Ahdy and Khaled (2009) classified CD in terms of four grade ratings of sediments, i.e.
CD < 6 shows low CD,
6 $\leq$ CD < 12 shows moderate CD,
12 $\leq$ CD < 24 shows considerable CD and
CD $\geq$ 24 shows very high CD.

***Where: L1** – Leachate at Choba dumpsite, **W1a** = Borehole water near Choba dumpsite, **W1b** = Borehole water about 10 km from Choba dumpsite. **L2** = Leachate at Ada-George dumpsite, **W2a** = Borehole water near Ada-George dumpsite, **W2b** = Borehole water about 10 km from Ada-George dumpsite.*

The result shows that the concentration in the leachate is far greater than that in the borehole water (both near and far away from the dumpsite) for the two dumpsites; except in pH. This shows that the leachates are more acidic in nature, indicating conditions undergoing active metabolic activities with higher organic materials. Higher BOD and COD in the leachate than the borehole water indicate that the leachate has higher organic strength than the borehole water which conforms to Zgajnar *et al*., 2008. Generally, W1a have more metal and anion concentrations at Choba dumpsite than W1b (Table 2, figure 2 and 3). TDS was higher in W1a than in W1b; however pH and EC are higher in W1b than W1a. This shows that W1a is more acidic and undergoing more metabolic phase than W1b, and the higher EC recorded in the W1b may be unconnected with the solids or salts that dissolve in water as it moves through the earth crust to distal end of the dumpsite. However, Ada-George dumpsite has higher TDS, pH, and EC in W2a than W2b (Table 2, figure 2 and 3). W2b that is more acidic than W2a may be as a result of reaction or hydrolysis of NO_3^- with other compounds to form acidic compound either before getting to W2b or on getting to W2b. Higher TDS in W2a than W2b shows that there may be higher decomposition rate at W2a than W2b; and that there are more organic material in W2a than W2b. High TDS recorded shows that significant organic components may have successfully entered the groundwater to increase its TDS. This shows that the borehole close to Ada-George dumpsite is gradually been polluted with dissolved organic substances.

IJSER

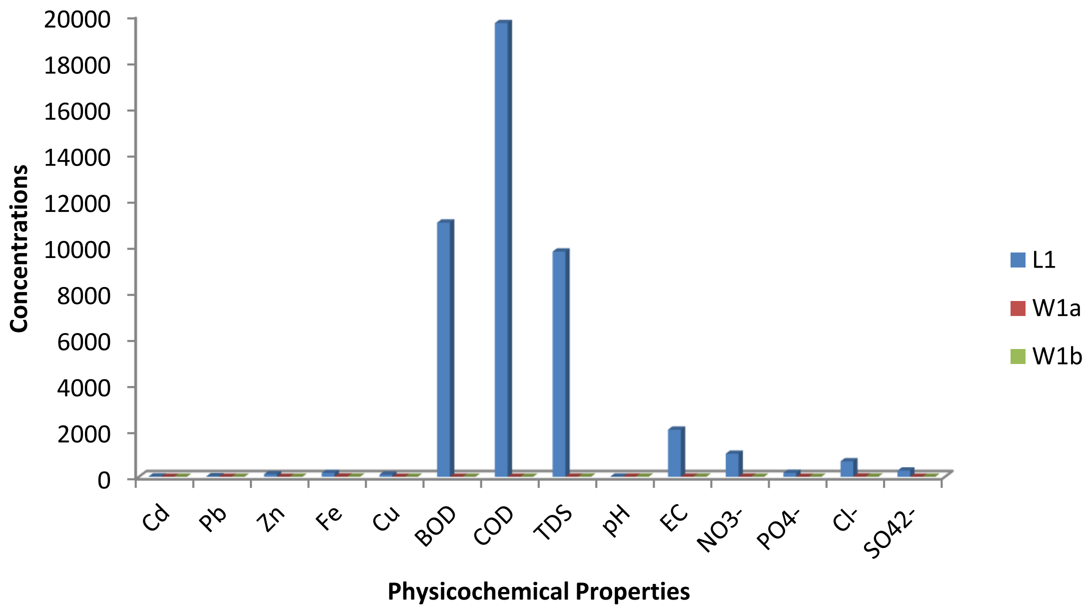

Figure 2: Figure showing metal and physiochemical properties in leachates and borehole water at Choba dumpsite

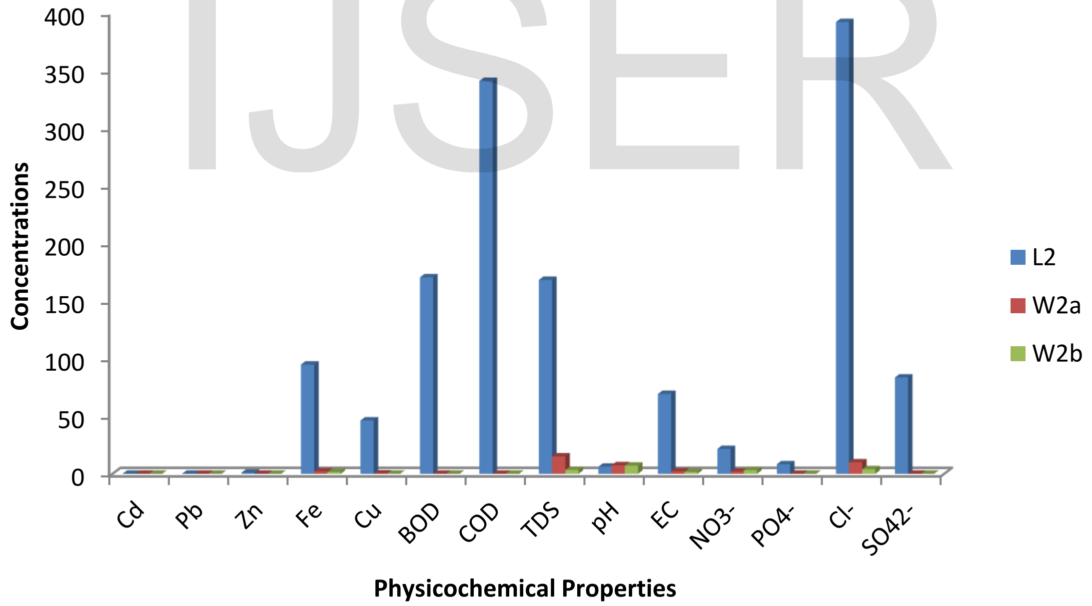

Figure 3: Figure showing metal and physiochemical properties in leachates and borehole water at Ada-George dumpsite

The two leachates, W1a and W1b has pH values slightly below the neutral value of 7 (L1=6.4, L2=6.2, w1a=6.7, W1b=6.9) which shows slight acidity. This condition therefore aids the dissolution of some metals and other pollutant in water thereby releasing toxic elements that may pollute groundwater. Low value of pH in the leachates than borehole waters is a strong reflection of an acid-producing phase during decomposition of wastes. According to Alloway (1995), the low pH value is an indication of leachate or water undergoing anaerobic or methanogenic phase. Fatta *et al*., (1998) observed that the initial period of leachate formation is characterized by very low pH values.

TDS is a reflection of the quantity of ionic or mineral constituents that are dissolved in the water. The EC obtained ranges from 69.30 S/cm in L1 to 2,040.1 S/cm in L1. The values recorded in the borehole water imply a reduction in concentration from leachate into borehole water, which conforms to Mor *et al.,* (2006) and Longe and Enekwechi (2007). The higher the TDS, the lower the palatability of water and may possibly cause gastro-intestinal irritation in human and laxative effects particularly upon transits (WHO, 1997). EC may be related to problems such as excessive hardness, corrosive characteristics or other mineral contaminations (Jain *et al*., 2010). High concentration of metal prevailed in the leachate.

Cadmium is widely distributed in the earth's crust. Human activities (such as mining, metal production, and combustion of fossil fuels) can result in elevated cadmium concentrations in the environment. Based on the data in table 2, L1 and the borehole close to Choba dumpsite (W1a) with Cd 12.6 and 0.04mg/L respectively did not meet NSDWQ (2007), WHO (2011) standard as they exceeds the maximum limit of 0.01 and 0.003 respectively. Other values of metals recorded are within limits of 0.01 and 0.003. Lead detected in samples originates from used batteries and other lead bearing wastes in the dumpsite. L1 (19.50) and W1a (0.20 mg/L) recorded high; which do not meet the standard set by NSDWQ (2007), WHO (2011). Traces of Zn were recorded in some of the sampled parameters. Except L1 (106.7), values of Zn in the sampled water parameters show that they are within the acceptable limits of NSDWQ and WHO. Cu was also recorded but below maximum limit or standard set by WHO and NSDWQ.

**All values in mg/L, except pH and EC (µS/cm);* NSDWQ *(2007), WHO (2011).*

In this study, leachate and borehole water concentrations of metals such as Cd, Pb, and Fe were identified in the analytes as have several potentially significant groundwater and public health challenges that require urgent attention and additional study as they exceeded the maximum limits set by WHO and NSDWQ health based drinking water criteria (see Table 3).

High concentration of anion also prevailed in the leachate than borehole water; with the least at the distant borehole. However, anion concentration in the borehole water is generally low and meets the standard set by WHO and NSDWQ. The major sources of NO_3^- are organic matter from man-made pollutants such as agricultural fertilizers (Ezeh *et al.*, 2016). NO_3^-

concentrations in the borehole water are very low, since plants are expected to take up most of the nitrogen near the ground surface before it can reach the water table. However, a level of NO_3^- in the leachate at Choba dumpsite (L1) is relatively high (998.60 mg/L). This can be explained by the fact that the land is contaminated by man-made pollutants such as agricultural fertilizers from nearby resident farmlands. NO_3^- concentrations in borehole samples near the dumpsites and at about 10 km away from the dumpsites were well within standards of WHO and NSDWQ. Phosphate ion concentration in L1 is 169.30 mg/L; and 8.30 mg/L for L2. Although the concentration of phosphate ion in the borehole water are low, it has been noted that a minute value of phosphate ion as low as 0.01mg/l in groundwater promotes the growth of algae (Adekunle *et al*., 2007). Though traces of chloride ion were detected in the borehole water, significant quantity was recorded in the leachates at the different dumpsites, which are more than the maximum permissible level stipulated by WHO and NSDWQ. The strong content in leachate chloride could only be of organic origin, because the ion chloride accompanies the ion nitrate in the case of groundwater pollution by domestic waste (Saadi, S. *et al*., 2014). The values of Sulphate ion (SO_4^{2-}) are lower than the standard of 100 g/L and 200mg/L set by WHO respectively for portable drinking water.

The result of the two respective dumpsites indicates that the concentrations of contaminants were found to be higher around the dumpsites than the one farther from it. This shows that the contamination drop with increase in distance from the dumpsite. Though the concentrations of few contaminants are negligible and may not have exceeded maximum drinking water standard, some exceeded the standard; and bioaccumulation of others can lead to increase in their concentration and possible side effects. The result conforms to Mor (2006) who emphasized in his study the strong relationship between depth and distance from landfills with underground water wells; where he noted that water samples taken from adjacent to landfills were the most vulnerable to pollution and decrease of contaminants result as the horizontal distance from landfills increase.

IJSER

The result of the Water Quality Index as shown in table 7 shows that both boreholewater around Choba dumpsite is poor (close to very poor with W1a = 195.48 and W1b = 192.36) as they contain considerable concentrations of contaminants. Ada-George borehole waters however have good water quality. Cadmium has very high CF of 13.33 in W1a, followed by Fe with 2.26 (moderate CF). Others in the borehole close to the dumpsite recorded low CF as they are less than 1. The distant borehole in Choba dumpsite however has low CF, with exception of Fe with 1.28 (which is moderate). Contamination Degree at W1a is greater than W1b (15.63 and 1.62 respectively). From the result obtained, W1a shows condiderable CD, while W1b shows low CD. It buttresses the fact that the borehole close to the dumpsite is more contaminated than the distant one. W2a and W2b show low CD.

4. CONCLUSIONS AND RECOMMENDATIONS

This study focussed on the effect of Municipal Solid Waste (MSW) leachate on ground water quality in Port Harcourt, Nigeria. Apart from quantitative and direct observation of data, Statistical Indices analysis using water quality index (WQI), contamination factor (CF), and contamination degree (CD) were successfully applied for the analysis. The result shows that some parameters did not meet the standards of WHO and NSDWQ; and most leachates and borehole water qualities near the unengineered dumpsites are of poor quality. There was a decreasing trend in concentrations of hazardous contaminants from the leachate to nearby borehole water and eventually the distant borehole water. This also shows that there is contaminants movement from the leachate along the water table through underground water aquifer to distant water boreholes. From this study we can conclude that there is an increase in risk to borehole and public health that is reported near the unengineered dumpsites; which can spread to other region on bioaccumulation. The result indicated that the dumpsite leachate is producing many potent contaminants to the environment and to the people nearby.

The following are therefore recommended.

1. Government with other environmental and public health organizations concerned should give prior attention to the problem of dumpsite, with regard to public health and ground water risks.
2. The operation of unengineered dumpsite should be stopped as soon as possible and new engineered landfill with proper collection and treatment of leachate be constructed.
3 Preventive management is the preferred approach to drinking-water safety and should take account of the characteristics of the drinking-water source of supply to its use by consumers.
