Status of Tree Volume Calculation and Development of Allometric Equations in Pakistan

Syed Moazzam Nizami

Abstract— This paper reviews and analyse the biomass and volume allometric models that have been developed for various tree species in forest ecosystem types in Pakistan. The mathematical form of the allometric model, the associated statistical parameters, as well as information about the size (tree diameter and height) and number of the sample trees used to develop models was collected from various sources published in scientific (both international and national) journals, student thesis and conference presentations. The total number of allometric models that have been reviewed in this paper are 18 consisting of 16 models for estimating biomass of tree components and 2 models for calculating stem volume. The spatial distribution analysis showed that these models have been prepared for dominant species of sub-tropical and coniferous sub-alpine forest ecosystems of Pakistan. These species include Acacia modesta (Phulai), Olea ferruginea (Kahu), Pinus roxburghii (Chir) and Betula utilis (Birch). In biomass models, both above and below ground biomass have been considered. Besides information on model distribution, data coverage, this paper analyses the gaps and proposed strategies to fill the gaps. The collected information on the models provides a basic tool for estimation of forest biomass based on its ecosystem type. This information also provides input to support the national carbon accounting system and estimation of carbon stock changes from greenhouse gas emission reduction and carbon stock enhancement in the land use sector.

Index Terms— Allometric models, Biomass, Tree volume, Forest ecosystem , Pakistan

1 INTRODUCTION

R eliability of the forest carbon and the understanding of the dynamics of carbon in forest ecosystem can be increased by applying the current knowledge concerning tree allometry in the form of volume and biomass allometric models [1],[2],[3]. The biomass allometric models can be used to directly estimate the stand tree biomass, from tree measurement data (diameter or combination of diameter and height) in forest stand inventory, or by adding specific gravity or wood density and the biomass expansion factor [4] or the biomass conversion and expansion factor [5] in using tree volume allometric models.

By using the allometric models that are already formulated, the biomass of one tree can be estimated just by entering the parameters of the results of the measured dimensions of the tree like diameter at breast height (dbh) and height. The stand biomass can be estimated by having information on stem density and then by extrapolating methods.

With Pakistan making attempts to implement REDD+, fulfill its reporting obligations of GHG emissions for the UNFCCC it is important that the appropriate models that are in accordance with UNFCCC guidance are adopted.

Currently, the guidelines or references related to the development of allometric models for estimating biomass and C stocks or determining local emission level in developing country given by Subsidiary Body on Scientific, Technical and Technological Advice (SBSTTA) and United Nations Framework Convention on Climate Change (UNFCCC) viz a viz IPCC GPG 2006 are being followed. Few allometric models to estimate tree biomass (including its components, e.g. stem, branches, leaves, twigs and roots) and tree stem volume that have already been developed are for few indigenous species in Pakistan. In order to use these allometric models as reference, a comprehensive study of tree biomass and volume allometric models that already exist is necessary. These models and allometric equations were developed during 2009-2014 in aspiration to assess the carbon stocks in different forest ecosystem in Pakistan by [6],[7],[8],[9].

The dominant species Acacia modesta, Olea ferruginea and Pinus roxburghii in sub-tropical forest ecosystem and Betula utilis in the coniferous sub alpine forest ecosystem were investigated. The methods described for biomass and carbon assessment developed by FAO 2004 [10] for land use were implemented in these assessments [6],[8].

This paper aims to serve as reference in estimating biomass through i) compilation and review on tree biomass and volume allometric models that have been developed for several tree species and forest ecosystem in Pakistan ii) to collect an allometric model development database to know the status of information currently available on tree allometry, identification on gaps of information and modelling methods. This paper also provides basic information on carbon stock assessments in the country and can be used as supporting instrument in implementation of REDD in the country.

2 MATERIAL AND METHODS

2.1 Data Collection

Literature review was conducted and biomass and volume allometric models were compiled in this paper. This included national and international scientific publications, seminar, conferences and university dissertations. The literature reviewed for this paper was limited to the publications till May 2014.

All information related to coordinates of the locations was recorded: i) location or research, details of the province, district or specific name of the forest ii) geographical position (latitude and longitude coordinates) iii) condition of the location (forest type, rainfall, temperature, altitude) and iv) stand...
condition (dominant tree species, stand age, stand density, stand height, basal area). Aside from this time when the research was carried out.

For allometric model following information was collected i) method of obtaining the sample tree ii) component or parts of the tree measured (stem, branches, sub branches, leaves, twigs, fruit, flowers and roots) iii) type of tree volume used for volume allometric model (total height / merchantable height etc) iv) methods for formulation of model v) no. of sample trees used to formulate the model vi) size of sample trees (diameter and height) vii) Variable used to formulate models viii) model form (linear, exponential, sigmoid, quadratic, power etc) and the ix) statistical parameters resulted from the model.

For the biomass several information, was recorded for examples methods of measuring the green weight of the biomass in the field, taking sub samples from every component for drying and weighing in the laboratory.

All locations of the area from where the models were developed has been shown on the map (Fig.1).

2.2 Evaluation of the Model

The main consideration in evaluating the models are statistical values, including i) unit value of the independent variable (x) and independent variable (Y) ii) value of the parameter coefficient iii) value of the standard error of the parameter and iv) the value of the coefficient of determination (R$^2$) that reflects the proportion of total variation of Y that can be explained by variation of X. Also the use of correction factor in these allometric models was evaluated [11],[12],[13]. The correction factor is primarily needed to eliminate the bias that is introduced when data was transformed (e.g. logarithmic transformation). However information on use of correction factor has not been represented in this paper as the studies used the correction factors is minimal.

Apart from the criteria above, evaluation was also carried out through testing by accounting the biomass values of individual trees based on the diameter of the sample trees used to formulate the model and comparing it with estimated biomass curve obtained from the model. An evaluation of qualitative performance of the model based on biological or logical consideration was also applied in this paper.

3 RESULTS

3.1 Geographical and Ecosystem Location of the Allometric Model

Each reference and location of the tree biomass and volume allometric model developed in Pakistan was classified according to forest ecosystem type to get information on spatial distribution of the availability of tree biomass and volume allometric model in Pakistan (Fig.1). Out of 19 models 6 (31.57%) were developed in sub alpine forests at geographical location of 34° 30' N and 72° 50' E while 13 models (68.43%) were developed in sub-tropical forest ecosystem at location of 33° 38' N and 73° 00' E.

3.2 Scope of the Allometric Model by Species

Of the total number of available biomass allometric models, all were developed for the natural forests. The number of species included in these models is four, namely; Acacia modesta (Phulai), Olea ferruginea (Kahu), Pinus roxburghii (Chir) and Betula utilis (Birch). The P. roxburghii is the only conifer species while the rest is broadleaved species.

Apparently the development of the volume allometric model has been slower than that of biomass allometric models. From the total number of available volume allometric models, 50% were developed for broadleaved and 50% for coniferous species. But all the dominant species were taken into consideration.

3.2 Tree Biomass Allometric Models

The total number of tree biomass allometric models presented in this paper is 16. These have been compiled and classified by forest type, tree species and location (Table 1). Most of the biomass allometric models (93.75%) that have been developed in Pakistan are for estimating above ground biomass of the tree species or the biomass of the individual tree components (Fig.2). There are still few allometric models (6.25%) developed for below ground biomass (roots). These models are mainly developed from the sample roots of small trees. This is because the root sampling is difficult and both time and cost consuming.

Based on the models developed in Pakistan, tree biomass allometric models are usually presented in polynomial quadratic form

$$y = y_0 + ax + bx^2$$

Where y (dependent variable) is the biomass; X (independent variable) is dbh or basal area, $y_0$ regression constant (not equal to 0) and a, b are the regression constant. Most allometric model for biomass presented in this paper are quadratic but in practice most of the researcher apply logarithmic transformation in process of fitting regression model using the least count square method in order to create the linear regression relationship and then back transformed into original arithmetic value to estimate the tree biomass. The transformation of biomass values to logarithmic value in the regression with the least square method leads to bias when logarithmic values turned back to original unit [11],[12],[13]. Nevertheless, this bias can be avoided by multiplying the result with the correction factor [12], [14]:

$$y = e^{(\mu + \sigma^2/2)}$$ if using natural logarithmic transformation

Or $$y' = e^{(\mu + \sigma \ln(10)^2/2)}$$ if using base 10 logarithmic transformation

Where $y$ is the estimated biomass value, $\mu$ average value of biomass, and $\sigma$ is the value of error variance.

The other alternative to avoid the linear logarithmic transformation is direct application non-linear regression methods, which can be found in the several statistical soft-
that over 97% of variation of volume data can be explained by
variation of diameter (in case of only variable used as an esti-

3.3 Tree Volume Allometric Models

The tree volume models that have been developed in
Pakistan are presented in(Table.2), classified according to eco-
system, tree species and location. In total , 2 volume allometric
models have been compiled in this paper. Similar to biomass
allometric model both the models have been presented in pol-
ynomial quadratic form. Among both the developed volume
allometric model single varaiable i.e dbh was used as volume estimator [7], [9]. Worldwide, the result of the regression anal-
alysis of volume allometric models showed that using addi-
tional height variable aside from diameter can improve the predic-
tion of 1-3% compared to using diameter variable only [15],
[16], [17]. Nevertheless, the additional time, staff and budget
required for the application in the field need to be considered
if tree height variable is to be considered.

In fact 5 trees were used for volume allometric model
development in ola ferruginea species of sub-tropical broad
leaved evergreen forest [7] and 10 trees were used for Betula utilis species in sub alpine forests [9].

The range of diameter (dbh) of the sample tree ranged
from 10-24cm. The trees of exploitable diameter (24cm) were
selected for O. ferruginea in sub-tropical broad leaved ever-
green forest while the trees of B.utilis were categorized into
three classes less than or equal to 10, 11 - 20 and greater than
or equal to 21 cm.

The value of the determination coefficient (R²) was
greater in both the volume allometric models. It was 0.99 and
0.97 for O. ferruginea in sub-tropical broad leaved evergreen
forest and B.utilis in the sub alpine forest [7], [9]. This shows
that over 97% of variation of volume data can be explained by
variation of diameter (in case of only variable used as an esti-
mator).

4 DISCUSSIONS

The results showed that the tree biomass and volume
allometric have been developed for only four species in three
forest ecosystem types in Pakistan. From the literatures that
have been reviewed following gap has been identified:

1. Identification of the locations that have not been investi-
gated and identification of new sources of information about the development of allometric models for estimating forest biomass at various locations in Pakistan. Information on spatial distribution of sampling location of allometric models, overlapped with the spatial distribution of forest ecosystem type in Pakistan can be used to identify these gaps. Therefore, to determine the location of the sample trees for measuring biomass in the field is necessary to consider the distribution and representation of the location.

2. The development of general allometric model specific to forest ecosystem type to cope with the diversity of ecological zones that exists in Pakistan.

3. Sample tree data used to develop allometric models should cover the range of tree diameter in the population (representing the existing distribution of diameter class) and the sample should be representative of the trees in order to produce statistically reliable results. Additional samples of large trees are required to expand the scope of available models, especially for tree species and forest ecosystem type for which large trees can still be found in the field.
