# A Buyer-Vendor EOQ model with time varying holing cost involving lead time as a decision variable under an Integrated Supply Chain system 

Sumana Saha , Tripti Chakrabarti

#### Abstract

In this paper, a supplier retailer inventory model is developed. Here, we describe an EOQ model with changeable lead-time and time dependent holding cost under an Integrated Supply Chain System. This situation is very common in the market, once an enterprise has some key technology or product that others have not, as a supplier, it can decide the prices and lead time of the technology or product to the buyers or retailers according to its need. Then the retailer determines his optimal order strategy, i.e., decides on the quantity of products to order from the supplier. Under this circumstance, the problem that lead time, as a controllable variable of the supplier, and how it affects the cost to the supplier, retailer and whole supply chain is very important to the supplier and retailer because double-win benefits is a base of existence for the supply chain. In this discussion, with a fixed market and lead time as a controllable variable, Retailer's Optimal Cost, Supplier's Optimal Cost, the optimal lead time of the supplier and order cycle time of the retailer, respectively, are investigated and approximate solutions for them are derived. Numerical examples are presented to compare results between the different demand rates and solved by using LINGO software. The Sensitivity analysis is carried out to analyze the effect of critical parameters on the optimal solutions.

Index Terms-EOQ, Time-dependent holding cost , Lead time , Integrated System, Supply chain, LINGO Software.

## 1 Introduction

In the last few decades, extensive researches have been performed in the area of supply chain coordination. A Supply Chain is a sequence of processes and flows that take place within and between different stages and combine to fill a customer need for a product .Traditionally, marketing, distribution, planning, manufacturing, and the purchasing organizations along the supply chain operated independently. Supply chains exist in both service and manufacturing organizations, although the complexity of the chain may vary greatly from industry to industry and firm to firm . Many manufacturing operations are designed to maximize throughput and lower costs with little consideration for the impact on inventory levels and distribution capabilities. Supply Chain Management is the combination of art and science that goes into improving the way your company finds the raw components it needs to make a product or service and deliver it to customers .

[^0]Supply Chain Management is a business practice that aims to improve the way a business sources its raw materials, and delivers it to end users. For any product or service offered by any business, there are usually a number of different business entities involved the various stages of the Supply-Chain, including manufacturers, whole sellers, distributors and retailers, the last group in a SupplyChain is consumers .
The Economic Order Quantity (EOQ) model, where cumulative holding cost is a convex function of time, is in contrast with the classic EOQ model where holding cost is a linear function of time. More specifically, the cumulative holding cost for one unit that has been stored during $t$ units of time is $H(t)=C_{1} t^{n}$, where $C_{1}$ and $n(\geq 1)$ are constants. If $\mathrm{n}=1$, then the problem reduces to the classic EOQ model with $C_{1}$ being the cost to hold one unit for one time period. Mark Ferguson et al. [6] studied a note: An Application of the EOQ Model with Nonlinear Holding Cost to Inventory Management of Perishables . Vinod Kumar Mishra [11] developed a Inventory model for time dependent holding cost and deterioration with salvage value and shortages. G.C. Mahata and A. Goswami [2] has used fuzzy concepts to develop a fuzzy EOQ model with stock-dependent demand rate and non-linear holding cost by taking rate of
deterioration to be a triangular fuzzy number. In recent years, EOQ research has many new directions, such as economic order quantity with random supplier capacity, quantity discounts for the vendor's benefit and the buyervendor coordination of inventory, ordering, pricing, etc. The aforementioned studies all assumed that the supplier's lead time is zero, or constant, that is to say, no stockouts are permitted in the model. S. Viswanathan [10] explained Optimal strategy for the integrated vendorbuyer inventory model. S.K. Goyal, and Y.P. Gupta. [9] reviewed Integrated inventory models: the buyer-vendor coordination. P. Piplani and S. Viswannathan [8] Coordinated supply chain inventories through common replenishment epochs. The traditional EOQ (economic order quantity) model focuses on the buyer's view and makes several assumptions, e.g., fixed market demand rate, no stockouts, unlimited supplier capacity and zero lead time, which are far from the actual requirements. In practice, such assumptions are rather difficult to realize . For instance, when the vendor has difficulty in supplying, there will be a deferred delivery problem and, as a result , the retailer can't replenish his inventory instantaneously. Another case is, when the supplier holds a monopolistic status, he will not only control products' prices but also their lead time in order to obtain the highest profits and the lowest cost. some researchers take into account the factor stockout in their research on the EOQ model and the lead time as a decision variable of the buyer . Liao and Shyu [1] proposed a model that can be used to determine the length of lead time that minimizes the expected total relevant cost for a continuous review policy where the order quantity and reorder level are known. The lead time is the only decision variable in many researchers' model. Hariga and Ben-Dayu [7] construct a continuous review inventory model where the reorder point, the ordering quantity and the lead time are decision variables. Models with full and partial information about the lead-time demand distributions are developed. J.M. Hsiao and C. Lin [3] considered a buyer-vendor EOQ model with changeable lead-time in supply chain". Yung-Fu Huang et al. [12] explained an easy approach to derive a buyer-vendor EOQ model with changeable lead-time in supply chain . Ben-Dayu and Raouf [5] constructed a model that considers both lead time and order quantity as decision variables . Later, Ouyang et al. [4] extended Ben-Dayu and Raouf's model considering shortages where the total amount of stockouts is considered as a mixture of backorders and lost sales. They assumed a given service level and therefore the reorder point is fixed.

In this article, we consider an EOQ model involving lead time as a decision variable with time varying holding cost on an Integrated System in the supply chain.That is, the distribution channel system contains one supplier and a single retailer and the supplier in the channel holds monopolistic status, in which he not only owns cost information about the retailer, but also has the decisionmaking right of the lead time . For example, the Ford Company sells automobiles to its dealerships, which in turn retail the automobiles to their potential customers. In this case, the automobile manufacturer represents the supplier and the dealerships represent the buyers. For those cases, the Ford Company is in a monopolistic position with respect to the dealerships. The supplier can decide its products' prices and lead time according to the situation, and the buyer then decides on the quantity of the products to order from the supplier, based on the supplier's products' prices and lead time. This situation is very common in the market. In this discussion, with a fixed market and lead time as a controllable variable, the optimal lead time of the supplier and order cycle time of the retailer, respectively, are investigated. The problem is then solved by using LINGO software.

## 2 Assumptions and Notations

We present here a continuous review, deterministic inventory model under the following assumptions and notations:

### 2.1 Notations and the basic model of the Retailer

The notations are defined as follows:
$Q \quad: \quad$ The retailer's initial inventory level (quantity)
$H(t)$ : The retailer's holding cost per product
$C_{2}$ : The retailer's stockout cost per product
$C_{3} \quad$ : The retailer's setup cost for each order
$D(t) \quad$ : Market's demand rate for some product
$f(t)$ : Total market's demand rate for some product from the beginning to time $t$, $f(t)=\int_{0}^{t} D(t) d t$.
$T$ : The retailer's order cycle time, a decision variable
Here the holding cost per unit increases with the time $t$ that the product has been in stock according to $H(t)=C_{1} t^{n}$, where $C_{1}$ and $n \geq 1$ are constants. Suppose the retailer's order cycle time is $t$ with no stockouts, then the average cost of the retailer in $t$ is
$T C_{r}(t)=\frac{C_{1}}{t} \int_{0}^{t} t^{n} f(t) d t+\frac{C_{3}}{t}$,
where $\frac{\mathrm{C}_{1}}{\mathrm{t}} \int_{0}^{t} t^{n} f(t) d t$ is the retailer's average holding cost in order cycle time $t$, $\frac{C_{3}}{t}$ is the retailer's average setup cost in order cycle time $t$.

### 2.2 Notations and the basic model of the Supplier

The notations are defined as follows:
A : The supplier's setup cost for each order
$h(t)$ : The supplier's holding cost per product
$L$ : The supplier's lead time, a decision variable, $L<T$

Here the holding cost is a linear function of time $t$ as $h(t)=$ $h_{1}+h_{2} t$ where $h_{1}, h_{2}>0$. Then the average cost of the supplier for dealing with his order is
$\mathrm{TC}_{\mathrm{s}}(\mathrm{t})=\frac{1}{\mathrm{t}} \int_{0}^{t}\left(h_{1}+h_{2} t\right) f(t) d t+\frac{\mathrm{A}}{\mathrm{t}}$,
where $\frac{1}{\mathrm{t}} \int_{0}^{t}\left(h_{1}+h_{2} t\right) f(t) d t$ is the supplier's average holding cost in order cycle time $t$, $\frac{\mathrm{A}}{\mathrm{t}}$ is the supplier's average setup cost in order cycle time $t$.

## 3 Cost models of the retailer and the supplier

In the distribution channel system with one seller and one buyer, in the buyer-vendor relationship, the supplier holds monopolistic status (leader) and the retailer is the follower. The leader, who has the ability to impose its strategies on the other player, declares its strategies first and imposes them on the follower. The follower then reacts to the leader's actions and decides on its strategies. when retailer's inventory is zero, he issues orders to the supplier immediately. However, the supplier always delivers the goods to him after a span of $L$ in order to get the biggest profits or for other reasons, that causes the retailer to be out of stock. As a result, customers have to buy the goods elsewhere, which is called loss sale . Additionally, the supplier possesses the information about the retailer's ordering and inventory cost, the supplier first announces whole sale price and lead time, the retailer then determines his optimal order strategy, i.e., decides on the quantity of products to order from the supplier .
(i) Retailer's average total cost in cycle $T$ :

Assume that the retailer's initial inventory level is $Q$, which can meet the demand for time $(T-L), f(t)=Q$ $\int_{0}^{t} D(t) d t$, during which the average inventory is $\frac{1}{T-L} \int_{0}^{T-L} f(t) d t$. The inventory in time $L$ is zero and its average stockout is $S=\frac{1}{L} \int_{T-L}^{T} f(t) d t$. For $Q$ is only
enough for demand over time $(T-L)$, then $Q=\int_{0}^{T-L} D(t) d t$, as shown in Fig. 1.
Thus, the retailer's average total cost in cycle $T$ is
$C_{r}(T, L)=\frac{1}{T}\left(C_{1} \int_{0}^{T-L} t_{n} f(t) d t-C_{2} \int_{T-L}^{T} f(t) d t+C_{3}\right)$
(ii) Supplier's average total cost in cycle $T$ :

The supplier's setup cost of orders is $A$, from beginning to time ( $T-L$ ), the retailer has some inventory and suppliers have to hold a quantity of products, which equals the market's demand for the product, i.e., that of the retailer's holding (see Fig. 1), so the supplier's holding cost is $\int_{0}^{T-L}\left(h_{1}+h_{2} t\right) f(t) d t$.
Thus, the supplier's average total cost in cycle $T$ is
$C_{S}(T, L)=\frac{1}{T}\left(\int_{0}^{T-L}\left(h_{1}+h_{2} t\right) f(t) d t+A\right)$

Fig. 1. The structure of the model

Combining Equations (3) and (4), we get the total average cost as follows
$T C(T, L)=C_{r}(T, L)+C_{s}(T, L)$

## 4 Evaluating Average Total Cost for different demand rates

(i) $D(t)=a e^{b t}$, where $0<b<1, t>0$, a $>0$, the market's demand rate for some product is exponentially increasing in nature.

Here $f(t)=Q-\int_{0}^{t} D(t) d t=Q+\frac{a}{b}\left(1-e^{b t}\right)$.
From $f(T-L)=0$, i.e., $Q$ is only enough for demand over time $(T-L)$, then we get

$$
Q=\frac{a\left(e^{b(T-L)}-1\right)}{b} .
$$

Thus, the retailer's average total cost in cycle $T$ from (3) is

$$
\begin{align*}
C_{r}(T, L)= & \frac{1}{T}\left[C_{1} \int_{0}^{T-L} t^{n}\left\{Q+\frac{a}{b}\left(1-e^{b t}\right)\right\} d t-\right. \\
& \left.C_{2} \int_{T-L}^{T}\left\{Q+\frac{a}{b}\left(1-e^{b t}\right)\right\} d t+C_{3}\right] \\
= & \frac{1}{T}\left[\frac{a C_{1}(T-L)^{n-2}}{n+1}\left\{\frac{1}{n+2}+\frac{b(T-L)}{2}\right\}+\frac{a C_{2} L^{2}}{2}\{1+\right. \\
& \left.\left.b\left(T-\frac{2 L}{3}\right)\right\}+C_{3}\right] . \tag{6}
\end{align*}
$$

and the supplier's average total cost in cycle $T$ from (4) is

$$
\begin{align*}
& C_{s}(T, L)=\frac{1}{T}\left(\int_{0}^{T-L}\left(h_{1}+h_{2} t\right)\left\{Q+\frac{a}{b}\left(1-e^{b t}\right)\right\} d t+A\right) \\
&=\frac{1}{T}\left[h_{1}\left\{\frac{a(T-L)^{2}}{2}+\frac{a b}{3}(T-L)^{3}\right\}+\frac{a h_{2}(T-L)^{3}}{24}\{4+\right. \\
&3 b(T-L)\}] . \tag{7}
\end{align*}
$$

Therefore, the total average cost in cycle $T$ from (5) is

$$
\begin{align*}
& T C(T, L)=\frac{1}{T}\left[\frac{a C_{1}(T-L)^{n-2}}{n+1}\left\{\frac{1}{n+2}+\frac{b(T-L)}{2}\right\}+\frac{a C_{2} L^{2}}{2}\{1+\right. \\
& \left.\left.b\left(T-\frac{2 L}{3}\right)\right\}+C_{3}\right]+\frac{1}{T}\left[h_{1}\left\{\frac{a(T-L)^{2}}{2}+\frac{a b}{3}(T-L)^{3}\right\}+\right. \\
& \left.\frac{a h_{2}(T-L)^{3}}{24}\{4+3 b(T-L)\}\right] . \tag{8}
\end{align*}
$$

(ii) $D(t)=\alpha \beta t^{\beta-1} ; 0<\alpha<1, \beta>0, t>0$, the market's demand rate for some product follows a twoparameter Weibull distribution.
Here $f(t)=Q-\int_{0}^{t} D(t) d t=Q-\alpha t^{\beta}$, from $f(T-L)=0$, we get $Q=\alpha(T-L)^{\beta}$.

Thus, the retailer's average total cost in cycle $T$ from (4) is

$$
C_{r}(T, L)=\frac{1}{T}\left[C_{1} \int_{0}^{T-L} t^{n}\left(Q-\alpha t^{\beta}\right) d t-C_{2} \int_{T-L}^{T}(Q-\right.
$$ $\left.\left.\alpha t^{\beta}\right) d t+C_{3}\right]$

$$
\begin{equation*}
=\frac{1}{T}\left[\frac{C_{1} \alpha \beta(T-L)^{n+\beta+1}}{(n+1)(n+\beta+1)}+\frac{C_{2}\left\{\alpha \tau^{\beta+1}-\alpha(T+L \beta)(T-L)^{\beta}\right\}}{(\beta+1)}+C_{3}\right] . \tag{9}
\end{equation*}
$$

and the supplier's average total cost in cycle $T$ from (5) is

$$
\begin{align*}
C_{s}(T, L) & =\frac{1}{T}\left[\int_{0}^{T-L}\left(h_{1}+h_{2} t\right)\left(Q-\alpha t^{\beta}\right) d t+A\right] \\
& =\frac{1}{T}\left[\frac{h_{1} \alpha \beta(T-L)^{\beta+1}}{\beta+1}+\frac{h_{2} \alpha \beta(T-L)^{\beta+2}}{2(\beta+2)}+A\right] . \tag{10}
\end{align*}
$$

Therefore, the total average cost in cycle $T$ from (5) is

$$
\begin{align*}
& T C(T, L)=\frac{1}{T}\left[\frac{c_{1} \alpha \beta(T-L)^{n+\beta+1}}{(n+1)(n+\beta+1)}+\frac{c_{2}\left\{\alpha T^{\beta+1}-\alpha(T+L \beta)(T-L)^{\beta}\right\}}{(\beta+1)}+\right. \\
& \left.C_{3}\right]+\frac{1}{T}\left[\frac{h_{1} \alpha \beta(T-L)^{\beta+1}}{\beta+1}+\frac{h_{2} \alpha \beta(T-L)^{\beta+2}}{2(\beta+2)}+A\right] . \tag{11}
\end{align*}
$$

## 5 Optimal Solutions L and T of the models

The objective in the following is to find the solutions for the optimal values of $T$ and $L$ (say $T^{*}$ and $L^{*}$ ) that minimize the total average cost $T C(T, L)$.
The necessary condition for minimization of $T C(T, L)$ are

$$
\begin{equation*}
\frac{\partial T C(T, L)}{\partial T}=0 \quad \text { and } \quad \frac{\partial T C(T, L)}{\partial L}=0 \tag{12}
\end{equation*}
$$

The sufficient condition for minimization of $T C(T, L)$ requires that it must be a convex function for $T>0, L>0$. Now, the function $T C(T, L)$ will be convex if

$$
\left|\begin{array}{ll}
\frac{\partial^{2} T C(T, L)}{\partial T^{2}} & \frac{\partial^{2} T C(T, L)}{\partial T \partial L}  \tag{13}\\
\frac{\partial^{2} T C(T, L)}{\partial L \partial T} & \frac{\partial^{2} T C(T, L)}{\partial L^{2}}
\end{array}\right|>0 .
$$

Equations(12) can be solved simultaneously by some computer oriented numerical technique to obtain retailer's optimal order cycle time $\mathrm{T}^{*}$ and supplier's optimal lead time $L^{*}$. For this, we have to prescribe the values of the parameters $C_{1}, C_{2}, C_{3}, A, h_{1}, h_{2}, \alpha, \beta, n$. As an illustration, we take up a numerical example.

## 6. Numerical Example

(i) To illustrate the model for exponential demand ,the following example is considered.
Let $C_{1}=2, C_{2}=8, C_{3}=100, A=200, h_{1}=0.2, h_{2}=0.1, a=$ $40, b=0.5, n=2$ in appropriate units.
Equations (8) and (12) are now solved simultaneously for the above parameter values using a gradient based nonlinear optimization technique (LINGO) and get the results shown in Table 1. It is verified that all the solutions in Table 1 for different values of $n$, satisfy the convexity condition for $T C(T, L)$.

Table 1 Optimal solutions for various values of ' $\mathbf{n}$ '.

(ii) To illustrate the model for Weibull distribution demand rate ,the following example is considered.
Let $C_{1}=2, C_{2}=8, C_{3}=100, A=200, h_{1}=0.2, h_{2}=0.1, \alpha=$ $0.6, \beta=20, n=2$ in appropriate units.
Equations (9) and (12) are now solved simultaneously for the above parameter values using a gradient based nonlinear optimization technique (LINGO) and get the results shown in Table 2. It is verified that all the solutions in Table. 2 for different values of $n$, satisfy the convexity condition for $T C(T, L)$.

## 7 Sensitivity Analysis

The sensitivity analysis is performed by changing the value of each of the parameters $C_{1}, C_{2}, C_{3}, A, h_{1}, h_{2}$ respectively by $-70 \%,-50 \%, 50 \%$ and $70 \%$, taking one parameter at each time and keeping the remaining parameters unchanged. We now study sensitivity of the optimal solution to changes in the values of the different parameters associated with the model. The results are shown in Table 3.

By analyzing the data in the Table 3, we can conclude that with the values of parameters increasing, the values of $L^{*}, T^{*}, C_{r}^{*}, C_{s}^{*}, T C^{*}$ all increase or decrease by degrees. The market's demand rate is the comparison between the demand rate $D(t)=a e^{b t}$ and $D(t)=\alpha \beta t^{\beta-1}$ in Table 3.
The effect of various parameters on decision variable and total cost of inventory system is exhibited in the following tables and figures.
Here we observe in Table 4 that $T^{*}, L^{*}, C_{r}^{*}, C_{s}^{*}, T C^{*}$ are all moderately sensitive to changes in $C_{1}$ for the case $D(t)=$ $a e^{b t}$ (See Fig.2).other side, for $D(t)=\alpha \beta t^{\beta-1}, \mathrm{~L}^{*}$ is highly sensitive and $\mathrm{T}^{*}, C_{r}^{*}, C_{s}^{*}, T C^{*}$ are less sensitive due to the changes in the value of $C_{1}$ (See Fig.3) .

## 8 Conclusion

This paper studies the optimal order strategy of the supplier and the retailer. When the supplier holds a monopolistic status, in which he controls not only products' prices but also the lead time, he actually controls the retailer's order cycle time. Such a control only benefits the supplier, not the retailer and the whole supply chain. If we take $h_{2}=0$ in Supplier's holding cost and $n=0$ in retailer's holding cost, then both holding cost become constant. In that case supplier will gain more profit compare to retailer. Taking holding cost and demand rate constant, some Researchers have developed a model where it is observed that supplier's average total cost decreases and the retailer's average total cost increases. Such a buyer-Vendor relationship greatly goes against the retailer and hardly
does any good to the distribution channel system. As a result, if the supplier makes some advisable concessions, then both sides can win. In this paper, we take timedependent holding cost for both supplier and retailer. Considering Exponential and Weibull demand rate, we notice that retailer's profit is higher than supplier's profit expect some of the results. So, retailer becomes more beneficial than the supplier in this type of model. In future the obtained optimal solutions can be improved by using different algebraic procedure or Geometric Programming Problem approach for the case of Posynomial functions which arises in Engineering problems.
