# Micro Grid Reliability Improvement Based On Smart Grid Techniques

M. A. A. MEHANNA, M.F. ABD ELAZIZ OMAR Department of Electrical Engineering, Faculty of Engineering, Al-Azhar University, Cairo, Egypt. Mehanna2002@hotmail.com , Mfomar80@gmail.com

Abstract- The electric utilities now a day in the way of modification from the traditional grids to smart grid. This modification improves in high significant action the reliability indices. Smart meter is considering one of the major component in smart grid. As smart meter improves the most important characteristic of smart grid which is the accurate and fast communication between grid component. This quick, and accurate information between grid component support the quick action needed to improve grid reliability specially both of the customer base indices, and the energy base indices. This paper will introduce how smart grids decrease the outage time and load, which reflect on SAIDI, CAIDI, ENA, and AENS indices. The paper will discuss two issues how smart grid affect the reliability indices over two different modules. First the impact of installing smart tools in conventional grid, which consist of commercial and residential loads. Second the load shedding technique within an existing smart grid of commercial loads, how this technique uses the spare generation power, and maintain system stability.

Index Terms – Smart Meter, Smart Grid, System average interruption duration index, Customer average interruption duration index, Energy not supplied, Average energy not supplied, Mean time to transfere switch, Mean time to repair, Operation Technology, Information Technology, Automated Feeder Switching, Fault Location Identification and System Restoration(FLISR), Power Management System(PMS)

### **1** INTRODUCTION

Now a day's utilities make an evolutionary change in the electricity infrastructure, and smart grid(SG) may hold that key of modernization and realization in grid [8]. So the main factors affect the decision of this revolution in changing the mind from traditional grid to smart grid is, how much there will be reliability improvement [4]. The goal for any utility that invests in smart grid technology is to attain higher efficiency and reliable performance [3]. A smart grid platform implies the convergence of Operations Technology (OT) – the grid physical infrastructure assets and applications-and Information Technology (IT) – the human interface that enables rapid and informed decision making. This paper describes best practices for migrating to a scalable, adaptable, smart grid network. [1,4]

In other word the Smart Grid is transforming utility operations and pushing IT across its traditional boundary into OT at a remarkable clip, rapidly blurring the distinction between the two categories [1]. This paper discusses

#### **2. RELIABILITY INDICES DEFINITION AND FORMULA** Customer Based Indices which are:

**SAIDI**: System Average Interruption Duration Index, indicates the total duration of interruption an average customer is subjected for a predefined time interval.

**CAIDI** Customer Average Interruption Duration Index, indicates the average time required to restore the service.

The other two indices are energy sales base indices which are:

the dynamics of IT and OT integration and how utilities can leverage this convergence for smarter, more cost effective, and more reliable operation [8].

Reliability indices which will be focused in this paper could be divided into two categories. Customer Based Indices, and energy based indices [5]. Both of the two categories could be used to assess the past performance of the grid. As mentioned before and after using the smart grid tools. Smart grid tools used also to target the reliability indices improvement, which done by two ways minimize the outage time and minimize the outage loads [2,4].

This fast and accurate mutual information exchange between smart grid componenet could help in the load management as shown in the second experiment in this paper. Help in grid stability specially if it is in island mode of operation [1,2].

**ENS** Energy not supplied by the system

**AENS** Average energy not supplied, AENS or Average system curtailment index, **ASCI** [3,7].

The reliability indices which will be measured by each technique will be calculated using the following input:

 $\lambda s = \sum_i \lambda i$  (*failure rate*) it is the number of failure of the net work item per year (1)  $Us = \sum_i \lambda i \times ri$  (Average Annual Outage Time) where ri is the estimated time to repaire. (2) rs= (Average Outage Time/Repair time)
(3)

Ni number of customers, Li load value in KW (4)

According to those previous data the indices will be calculated as follow:

**SAIDI**= (Sum of customers interruption duration / total no. of customers)  $\sum (U_i \times N_i) / \sum N_i$ 

(Hours/customer year)

**CAIDI**=Sum of customer interruption dura-3- Installing Smart Grid Component in Convention

## 3- Installing Smart Grid Component in Conventional Grid to Minimize Outage Time

Using Smart meters is one of the major benefits of investing in smart grid technologies, tools, and techniques include faster utility responses to power outages and the ability to restore services more quickly compared to traditional outage management techniques. Traditional distribution grid could be converted to micro grid in brief by the following steps.

First Distribution automation, including automated feeder switching (AFS) and fault location isolation, and service restoration (FLISR).

tions/total no. of customer interrupted  $\sum (Ui \times Ni)$ / $\sum (Ni \times \lambda i)$  (hours/customer interruption) ENS=L(KW)\*U (Outage duration) (KWh/yr) = $\sum (Ui \times Li)$ AENS (Average energy not supplied) calculated by dividing the ENS over the total number of cus-

by dividing the ENS over the total number of customers  $= \sum (Ui \times Li)$  / $\sum (Ni)$  (KWH/CUSTOMERS/YR) [6,7]

The utilities that use AFS for FLISR operations are improving their electric reliability indices such as CAIDI and SAIDI and helping to improve grid reliability.

Second Integrating Advanced Metering Infrastructure (AMI). Where there will be comparison in the outage time over two case of study. First the repaire time including (repaire time + fault location identification) in conventional case(Fig1). where conventional grid over the medium voltage level (22K.V) with total loads(6.2MVA)

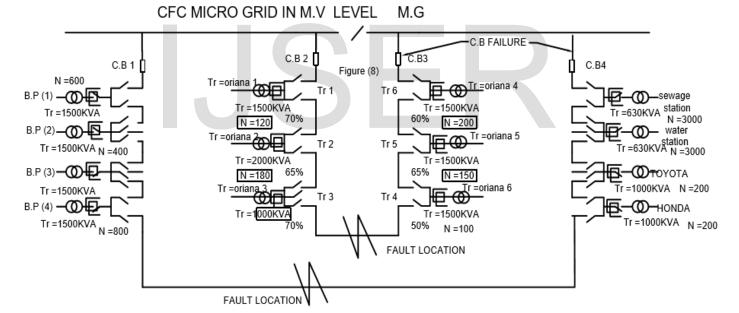

Fig.1 conventional grid without smart component installation

IJSER © 2017 http://www.ijser.org

Second the repaire time (repaire time + fault location identification) after adding smart tools to conventional grid.

## 3.1 Conventional grid- (base case) 3.1.1 Grid description

\*It is medium voltage level grid consist of residential, commercial, and service loads.

\*Total load 6.208 MVA

\* Number of person use this grid 8700

\*In this module there will be cable fault located between

#### BP4 and Honda building

\* According the normal procedures the Rt repaire time = Fault Location Identification+cable repaire time

\* rt = FLISR (fault location identification & service restora-

tion) (30 minute) + CRT (cable repaire time)

(120 minute) =2:30 hr

## This is the traditional procedures followed by operation **3.1.2 Indices Computation Assumption**

1-The period of MTTS (mean time to transfere switch) between isolation of the loop from the main feeding of Micro grid and Gen. Startup individually for each building is nearly 5 min. (0.083 hr.)

2-The MTTR (mean time to repaire) the fault in the mentioned loop will be identified according operation procedure will be within 30min.

3-The repair time (Rs) could be calculated using this formula Repair TIME (rs)

Table 1 reliability indices calculation in base case- conventional grid

and maintenance team to identify the fault location: Switch off CB no. 4

Switch off all L.B.S of all RMU connected to this loop Begine to connect in cascading order each load starting from B. P1 till the sewage station.

Till trip occure again

There for the crew know the faulty zone and isolate, and continue feeding the rest of the loads.

= (MTTS. \*gen%of load coverage) + (MTTR. \*%of un covered loads)

4-Assume that Gen. (Failure per year f/yr.=5%) and percentage of Gen. reliability95%

5-Outage time= [rs\*95%] + [ MTTR\*5%]

6-N is the no. of customers. Table (1) show the reliability indices values in this scenario. The (FLISR) will be 30 minute this is in addition to the main repaire time of the cable 2 hr.

### **3.2 Installation of smart tools.**

### 3.2.1 Steps of conversion to smart grid

In this case traditional grid changed to smart by the following action:

Modify all the L.B.S(load break switch) to be motorized and provided with auto reset circuit

There will be P.T (potential transformer) &C. T (current transformer) installed over the cable head connected with the R.M.U(ring main unit)

There will be micro controller connected to the trip circuit and auto reset of each R.M.U

There will be main logic controller (auto reclosure) connected with smart meter installed at start & end of each loop.

### 3.2.2 Indices computation basis and assumption after installing smart component

The time of fault location identification will be decreased from 30 min to 3 minute due to the following procedures as shown in fig.2. All the data of each R.M.U (voltage, no. of switching, L.B.S address no., L.B.S status – on or off)

The communication between the smart meters could be used as data bus showing the following details:

Power flow

Losses of each Tr.

R.M.U switching information

Voltage profile (swelling and spikes, any partial discharge) early detection for any insulation failure

Complete current profile (indication for any harmonic effects, unbalanced loads, power factor, predicted no. of customers at this moment).

All the R.M.U along the loop will be tripped off and begin to reclose automatically in cascading order, where the feeding will be through one side only let it C. B1

IJSER © 2017 http://www.ijser.org The R.M.U will be connected (reclosed- first reclose) one after the other (starting from B. P1 to sewage)

There will be time lag near to 3 second between each R.M.U switching and the other

Till connecting B. P4 instantenously C. B1 and all the R.M.U in this branch will be tripped.

By this way the fault will be identified by the first reclose that the fault is between B.P4 and HONDA

When C. B4 connected in the same action happened where the fault isolated and identified and all the smart meters will communicate showing the power flow directions The presence of smart meter and due to the instantenous trip. The smart meter register the current value, and report back to stop the second reclose in the motorized LBS(load break switch). The second reclose will take action again over all LBS of all the loads in the loop except outgoing(honda&BP4).

In this case the repaire time will be (MTTR of the cable(2 hr)+FLISR fault location identification (3 min)).=2:3 hr .Table (2) show the indices values after decrease the FLISR from 30 minute to 3 minute.

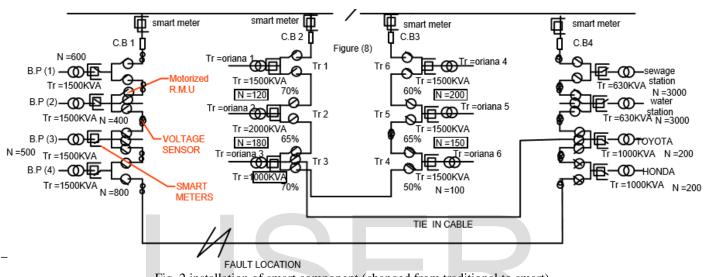

Fig. 2 installation of smart component (changed from traditional to smart)

Fig(3) show the indices values and the improvement percentage. How the usage of smart tools decreases the total repaire time by 27 minute. The improvement impact is high significant in both customer, and energy base indices

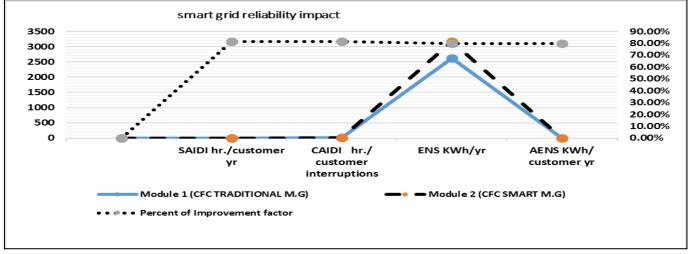

Fig 3 The improvement in reliability indices before and after smart tools

## 4- load shedding technique in smart grid.

Load shedding technique is aimed directly to maintain grid stability, and to prevent sudden blackout. The loadshedding system has three requirements.

Minimize process disruption

Work under all system topologies (bus configurations) Operate in 60 m s or less

The primary scheme (Base-Case) uses a comprehensive power management system (PMS) that calculates predicted power deficits resulting from predetermined events (contingency based), using system inertia and governor response models for system generators. Knowing the spare in each generation unit versus the existing loads. This scheme will be executing in blind action in base case. In base case there will be spare generation will be used in case of island mode for this grid.

The secondary scheme (load shedding technique) is based on the following givings (pickup of under frequency relays, actual load value, using system inertia and governor response models for system generators, and satisfaction of the stability condition). The objective of the secondary scheme is to minimize the outage loads in case of the system frequency drops below operator defined thresholds. where there is no feed back of the load case. The feed back will be the system frequency pickup value, and according to that the load shedding will apply the priorities planes in cascading order till system frequency adjustment.

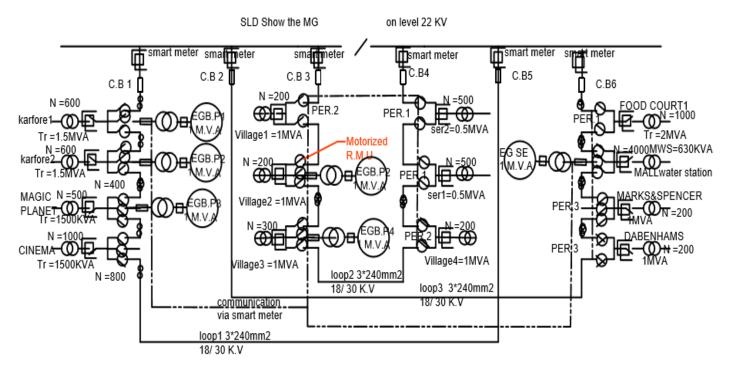

Fig.4 MV level grid in island mode showing (covered & uncovered loads)

## 4.1 Smart grid in island mode without load shedding techniques(base-case)

As shown in fig 4 the M.V network in case of a disturbance in the main grid. this mentioned network isolated from the rest of the project. During isolation from the main

## 4.1.1 Grid Description

In this case, there will be isolation to the shown smart grid, which is group of loads connected to each other over the medium tension (22K.V). In case of normal feeding those loads, which estimated to be 6402 K.V.A after the diversity factor where there must be two action had been taken.

**First**: each mentioned load had a backup generator as mentioned in table 4 make start up and synchronized with the other backup generation over the medium tension grid as shown in Fig.4.

Second: backup generation will form Micro grid try to share each other to fed the loads without back up generation.

grid those units of generation synchronized one after the other over M.V level, this synchronization offers the load sharing where uncovered load also could be covered.

module (where there was shutdown suddenly happened in back up generation of karefor2) the load suddenly divided over the other backup generation. This will lead that most of the MCB (main circuit breakers) of the MDB (main low voltage distribution board) will trip over load. As each CB of the MDB is adjusted to tripe be triped within 1.2 of (nominal current) represent 0.8 of rated output current of backup generation.

**Fourth**: each back up generations returned back again to feed its own load only. Where there willnot be load sharring any more.

**Third**: in case of disturbance simulation as shown in this

Table (4) loads value, spare generation power and grid stability condition in island mode.

### 4.1.2 Reliability indices computation assumption in base case (without load shedding)

The period of MTTS between isolation from the main grid and forming Micro grid till generators start up individually for each load and synchronizing with other generation is nearly 5 min. (0.083 hr.)

The MTTR either there is fault in the micro grid or there is temporary mechanical disturbance in the generator will take time to repair = 30 minute.

The repair time (Rs) could be calculated using this formula Repair TIME (rs)

= (MTTS. \*GEN%OF LOAD COVERAGE) + (MTTR. \*%of un covered loads)

Assume that Gen. percentage of failure per year (f/yr=5%) and percentage of Gen. reliability95%

Outage time= [rs\*95%] +[ MTTR\*5%]

N is the no. of customers.

The indices had been computed based on the scenario that

there is disturbance in (Carefore 2 Generation). In this scenario the islanded grid stability condition will be affected. This disturbance leads to the outage of all the uncovered loads.

The blind action of the under voltage frequency pickup relay will disconnect all the uncovered loads to maintain system stability.

Table (5) show the reliability indices without using the load shedding device. The grid in island mode will disconnect all the uncovered loads in blind action. Based only on the under voltage frequency pickup relay all the uncovered loads will still disconnect till the grid mode of operation changed from island mode to connected mode.

## **4.2 Smart grid in island mode with load shedding techniques 4.2.1 Grid description**

In this case the only addition is the load shedding device, which is connected with the CB of the MDB through the smart meter. This load shedding device which is programed according to the component address to apply the priority scheme. Using the smart meter as data bus to exchange the information and trip signals. When disturbance happened in karefore 2 generation this will lead to the underfrequency sensed by the load shedding device. Which apply the priority scheme in higher and shortest Table 6 (Load shedding perriority scheme) time response than the under voltage protection. Table4 illustrates the selected load-shedding scheme to protect overload condition and accordingly maintain system Stability. System inertia and the frequency band between pickup levels predicate the upper constraint on the selection of pickup time. Based upon these considerations, each generator operates separately, the pickup time of 0.1 seconds for all load-shedding steps is proposed through the simulation case studies.

|                    | 1 5 /         |                           |                    |                |
|--------------------|---------------|---------------------------|--------------------|----------------|

|                    | Village2      | 1000*50%                  |                    |                |
| 3                  | Village3      | 1000*40%                  | 49.2               | 0.18           |
|                    | Village4      | 1000*40%                  |                    |                |

Table (6) also based on the main fact that according to the value of under frequency the shedding priority will be first to the unit that is not shared with emergency Generator set. Also will be based up on the type of activity.

### **4.2.2Reliability indices computation assumption (with load shedding)**

It will be the same assumption as mentioned before in

(4.1.2), but with difference in the covered load.

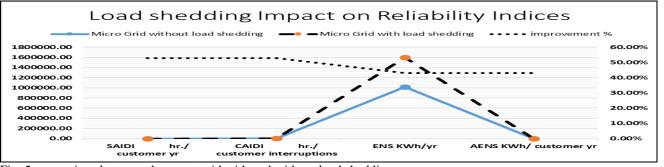

In this case when disturbance happened in carefore2 the load shedding will apply the priority scheme. According to this scheme as mentioned in table 6 step 1& 2 loads will be disconnected. From the grid leave priority one connected. The grid maintains it's stability where reliability indices will be calculated based on those inputs as follow: The repair time (Rs) could be calculated using this formula Repair TIME (rs)

Table (7) reliability indices calculation with load shedding

## = (MTTS. \*GEN%OF LOAD COVERAGE) + (MTTR. \*%UNCOVERED LOADS(step1&2))

Table (7) show the reliability indices after using load shedding technique, how the indices improved after appling the priority one, and two in load shedding scheme. table 8 and fig.5 show the comparison between the smart grid with and without load shedding.

## **Conlusion:**

Smart grid provides solutions to decrease both of the outage time, and outage loads.

The customer base indices is affected directly by the outage time (Ui), where the energy base indices is affected directly by load outage (Li). Smart grid achieves minimizing the outage time by (quick identification for fault location which estimated according to the manual operation record to be in average 30 minute where ever the fault location), this smart tools identify, and clears the faulty zone within 3 minute, and offer secure feeding source.

In the first issue the convertion from traditional to smart grid provide a good solution to decrease the repaire time from 2:30 hr to 2:03 hr. Decrease the repaire time by 27 minutes, the 27minute is the time needed for fault location identification and service restoration (FLISR). This is done by the first and second reclose of the automized switchgear. The quick mutual exchange between grid component using the smart meter as data bus lead to minimize the time of clearing the faulty zone.

The second issue in this paper show how the outage loads could be minimized using the load shedding technique. The second module is commercial and service grid, where in island mode the only covered loads is the loads provided with backup generation. In case of the presence of smart grid component in this commercial grid, the load shedding offers a good solution to use the spare of generation in each backup unit The presence of smart tools and the quick mutual data exchange between grid component (actual loads, frequency level, and generation governer response) provide suitable accurate data. These accurate data made the load shedding device achieve priorities planes for system stability. This technique decreases the outage loads, and maximize the usage of spare generation in case of islanded mode.
